Abstract

Multiple metrics have been introduced to measure fairness in various natural language processing tasks. These metrics can be roughly categorized into two categories: 1) extrinsic metrics for evaluating fairness in downstream applications and 2) intrinsic metrics for estimating fairness in upstream contextualized language representation models. In this paper, we conduct an extensive correlation study between intrinsic and extrinsic metrics across bias notions using 19 contextualized language models. We find that intrinsic and extrinsic metrics do not necessarily correlate in their original setting, even when correcting for metric misalignments, noise in evaluation datasets, and confounding factors such as experiment configuration for extrinsic metrics.

1 Introduction

Recent natural language processing (NLP) systems use large language models as the backbone. These models are first pre-trained on unannotated text and then fine-tuned on downstream tasks. They have been shown to drastically improve the downstream task performance by transferring knowledge from large text corpora. However, several studies (Zhao et al., 2019; Barocas et al., 2017; Kurita et al., 2019) have shown that societal bias are also encoded in these language models and transferred to downstream applications. Therefore, quantifying the biases in contextualized language representations is essential for building trustworthy NLP technology.

To better understand the relationship between intrinsic and extrinsic fairness metrics, we conduct extensive experiments on 19 pre-trained language models (BERT, GPT-2, etc.). We delve into three kinds of biases, toxicity, sentiment, and stereotype, with six fairness metrics across intrinsic and extrinsic metrics, in text classification and generation downstream settings. The protected group domains we focus on are gender, race, and religion.

Similar to the observations in static embeddings (Goldfarb-Tarrant et al., 2021), we find that these metrics correlate poorly. Therefore, when evaluating model fairness, researchers and practitioners should be careful in using intrinsic metrics as a proxy for evaluating the potential for downstream biases, since doing so may lead to failure to detect bias that may appear during inference. Specifi-
cally, we find that correlations between intrinsic and extrinsic metrics are sensitive to alignment in notions of bias, quality of testing data, and protected groups. We also find that extrinsic metrics are sensitive to variations on experiment configurations, such as to classifiers used in computing evaluation metrics. Practitioners thus should ensure that evaluation datasets correctly probe for the notions of bias being measured. Additionally, models used to compute evaluation metrics such as those in BOLD (Dhamala et al., 2021) can introduce additional bias, and thus should be optimized to be robust.

The main contribution of our work is as follows: First, we conduct an extensive study on correlations between intrinsic and extrinsic metrics. Second, we conduct ablation studies to show the effect of (mis)alignment of notions of bias and protected groups, and noise in recent fairness evaluation datasets. Finally, we conduct a study on the robustness (or lack thereof) of sentiment classifiers to text generation quality, diversity, and noise.

With this paper, we aim to suggest preliminary best practices in bias evaluation, which is important to quantify progress in debiasing work that will make models usable in the real world.

2 Fairness Evaluation Metrics

The notion of bias we focus on is group disparities in sentiment, toxicity and stereotypes, which have been extensively researched in the context of fairness (Huang et al., 2020; Zhang et al., 2020; Borkan et al., 2019; Adragna et al., 2020). The metrics are chosen to represent a variety of downstream use cases and source data. We use CEAT and ILPS for intrinsic metrics for toxicity and sentiment, HATEX, TOXD, and B-TOX for extrinsic toxicity metric, and B-SENT for extrinsic sentiment metric. For stereotype, we use STEREOSET and B-S-TEREO for intrinsic and extrinsic metrics.

**Intrinsic: Contextualized Embedding Association Test (CEAT)** (Guo and Caliskan, 2021) measures bias through word embedding distances in semantic vector space. Given a set of protected group (e.g. “woman”) and two polar attribute sets (e.g. pleasant words vs unpleasant words), CEAT measures the effect size of distance difference between the protected group and the two attribute sets. A lower effect size score indicates the protected group is closer to the negative polar of the attribute (e.g. unpleasant) and thus probably more correlated with toxic words.

**Intrinsic: Increased Log Probability Score (ILPS)** (Kurita et al., 2019) measures bias on word associations between protected groups and attributes with templates such as “The [group] is <mask>.” It computes the increase in probability of the attribute (e.g. “happy”) for the <mask> token given a protected group (e.g. “woman”). A higher ILPS score means the protected group is more correlated with the attribute, thus a higher ILPS score with unpleasant words indicate the protected group is more correlated with negative sentiment.

**Intrinsic: StereoSet** (Nadeem et al., 2020) measures bias in language model scoring of stereotyped sentences over anti-stereotyped sentences. Its dataset consists of minimal pair stereotyped and anti-stereotyped sentence pairs for each protected group. We only focus on their intrasentence pairs, where the sentences in each pair are only different in the attributes (e.g. “The Iranian man might be a terrorist individual” and “The Iranian man might be a hardworking individual” is a sentence pair for Iranian group). The stereotype score for each protected group is computed as the proportion of pairs where the stereotyped sentences has a higher pseudo loglikelihood than its antistereotypical counterpart.

**Extrinsic: Jigsaw Toxicity** (TOXD) (Jigsaw, 2019) measures bias in toxicity detection systems that covers multiple protected groups. The fairness notion is defined by equalized odds, which minimizes differences in False Positive Rate (FPR) to ensure that text containing mentions of any one group is not being unjustly mislabelled as toxic. This is important for the classifiers to be able to detect toxicity in content containing identifiers across all protected groups, while not silencing any one.

**Extrinsic: HateXPlain** (HATEX) (Mathew et al., 2020) measures bias in hate speech detection systems. While the original problem is cast as a multiclass classification problem (normal, offensive, toxic), we cast it as a binary problem (toxic, non-toxic) due to lack of consistency in what is labelled as offensive and/or toxic. Similar to TOXD, the measure of bias against a certain group is the False Positive Rate on examples with group mentions.

**Extrinsic: BOLD** (Dhamala et al., 2021) is a dataset that measures bias in language generation that consist of Wikipedia-sourced natural prompts. Given a prompt containing direct or indirect mentions of a protected group, BOLD evaluates the
quality of the sentences finished by the language model. We focus on the sentiment (B-SENT) metric for sentiment, toxicity (B-TOX) metric for toxicity, and regard (B-REGARD) metric for stereotype. Additionally, for stereotype, we train a stereotype classifier by finetuning the BERT model with Stere-oSet (Nadeem et al., 2020), CrowS-Pairs (Nangia et al., 2020), and Social Bias Frames (Sap et al., 2020) datasets, and use this classifier to evaluate BOLD generations on stereotype (B-STEREO)\textsuperscript{3}.

The bias score for each protected group is calculated as the average toxicity, sentiment, regard, and stereotype score on the generations from the prompts with that protected group.

3 Correlation between Metrics

**Experiment Setup** We conduct a study on gender, race, and religion domains (see the Appendix A for the list of protected groups on each domain). We conduct correlation analysis on the variance of group metric scores across protected groups, as it captures score disparities across protected groups for each domain. For example, for \( M = \text{CEAT} \), we define \( S_{M_{\text{race}}} = \text{Var}(s_{\text{Asian}}, s_{\text{White}}, s_{\text{Black}}, \ldots) \). A less-biased model would have smaller variance score. Thus, if two metrics are correlated, we would see a positive correlation, as reducing the disparity between groups in one metric, as measured by variance would reduce that in the other.

We evaluate 19 popular pre-trained language models\textsuperscript{4}. These models consist of ALBERT (Lan et al., 2020) (base-v2, large-v2, xlarge-v2, xxlarge-v2), BERT (Devlin et al., 2019) (base-cased,large-cased), RoBERTa (base, large), DistilRoBERTa (Sanh et al., 2019), GPT2 (Radford et al., 2019) (base, medium, large, xl), DistilGPT2, EleutherAI/gpt-neo (Black et al., 2021) (125M, 1.3B, 2.7B), and XLNet (Yang et al., 2019) (base-cased, large-cased)\textsuperscript{5}. For intrinsic metrics, we simply measure the corresponding metric scores on the language models\textsuperscript{6}. For extrinsic metrics, we fine-tune language models for classification-based tasks\textsuperscript{7}, and either sample in an autoregressive manner for autoregressive language models, or use random masking-based generation for MLM-based models (Wang and Cho, 2019) following the BOLD paper, for generation-based tasks\textsuperscript{8}.

For each intrinsic and extrinsic metric pair, we take the intrinsic and extrinsic scores for each et al. (2021) for the religion domain.

\textsuperscript{3}The stereotype classifier reaches a F1 score of 0.80 on the validation dataset. See Appendix B for training details.

\textsuperscript{4}Code are available at https://github.com/pruksmhc/fairness-metrics-correlations

\textsuperscript{5}We pick the most popular models for both masked language models and generative language models from HuggingFace https://huggingface.co/models.

\textsuperscript{6}We use the same experiment settings, such as testing word choices, testing dataset, etc., as proposed in the papers where these metrics are introduced. CEAT does not cover groups in religion, so we adopt the protected group list from Sotnikova et al. (2021)

\textsuperscript{7}For classification tasks, we use the hyper-parameters for fine-tuning language models on tasks for extrinsic metrics that achieve close to state-of-the-art F1 score (see Appendix C). Some language models are not suitable for the generation task due to the nature of the language model’s pre-training method. Thus we exclude these models, including ALBERT, DistilRoBERTa, and XLNet models, for BOLD-related extrinsic metrics calculation.

Correlation Results Table 1 contains correlations scores for each intrinsic/extrinsic metric pair on sentiment and toxicity. Only few metrics have significantly positive correlations. In general, ILPS has more significantly positive correlations with the extrinsic metrics compared to CEAT, except for the religion domain. This may due to the nature of the two intrinsic metrics – ILPS is calculated with log probabilities, which is more related to the downstream generative tasks such as BOLD since generation samples based on log probabilities.

For sentiment metrics, we find more statistically significant positive correlations between intrinsic metrics and B-SENT than toxicity extrinsic metrics.

In both toxicity and sentiment, we see that there are statistically negative correlations for the religion domain, which we investigate in Section 3.2.

For stereotype, Table 2 contains the results on stereotype metrics. We see that none of the correlations are significant nor positive.

4 Ablation Study

There are many factors at play in fairness evaluation processes, such as notion of bias measured, choice of protected groups, quality of the testing data, and confounding factors in the models used to compute metrics themselves. In this section, we conduct careful analysis to explore why extrinsic and intrinsic metrics are not always correlated.

4.1 Misalignment between metrics

In our main study, we use the experimental settings defined in their original papers. However, these metrics may have subtle misalignments in type of bias measured, protected groups factored in calculation, and characteristics of the evaluation dataset.

Misalignment on the notion of bias Among the toxicity metrics, the notion of bias are not consistent – some measure sentiment (CEAT, ILPS, B-SENT) while others measure toxicity. Therefore, we recompute CEAT scores with toxicity word seeds, which we denote as CEATTOX. We manually pick 20 toxic and 20 anti-toxic words from the word clouds of the toxic and non-toxic labeled sentences in the JigsawToxicity dataset for CEATTOX. See Appendix D for the full list of the words.

As seen in Table 3, the correlations between the toxicity-related extrinsic metrics and CEATTOX are more positive than with CEAT. Also note that CEAT is better correlated with B-SENT than CEATTOX, except for religion. Though many of the correlation scores remain not statistically significant, the result supports our hypothesis that intrinsic and extrinsic metrics are more correlated when they have the same notion of bias.

Misalignment on the protected groups Due to the limited number of overlapping protected groups (stereotype metrics only have four groups in common), we compute the domain-level variance scores for all protected groups contained in a dataset. However, the groups that are not present in both the evaluation datasets for intrinsic and extrinsic metrics may introduce metric disalignment, as they would be factored in metric computation in one but not the other. We recompute the correlation of STEREOSSET with B-REGARD and B-S with only overlapping protected race groups9: White, Black, Hispanic, and Asian.

We find the correlation of STEREOSSET with B-REGARD raises from $-0.08$ to $0.19$ (p-value 0.56). The correlation with B-S increases from $-0.18$ to $0.08$ (p-value 0.80). These metrics are more positively correlated with the aligned groups.

Misalignment on evaluation dataset We observe that dataset sources for certain metrics are misaligned, such as that for BOLD and STEREOSSET. STEREOSSET uses crowdworkers to generate testing data specifically to contain particular

---

9STEREOSSET does not have group Asian and White, so we use Japanese and Britain instead for these groups.
stereotypes. On the other hand, BOLD prompts are sourced from Wikipedia, which consist of more formal writing and is not directly engineered to probe for stereotypes. Examples of source misalignment can be seen in the Appendix.

To align the stereotype metrics, we use data from the STEREOSet intersentence dataset, which consists of a one-sentence context followed by a relevant stereotyped sentence, to compute BOLD metrics. Specifically, we use the context sentence for BOLD-like generation (see Appendix F for generation examples). We test STEREOSet with the new B-STERE0 on the race domain and find that the correlation score increase from $-0.18$ to $0.02$ (p-value 0.98). This indicates that aligning the evaluation dataset source has a modest impact on improving correlation between metrics.

### 4.2 Noise in Evaluation Datasets

As pointed out in Blodgett et al. (2021), some fairness evaluation datasets lack consistency in framing and data collection methodology, which leads to datasets not properly evaluating the intended notion of bias. We find evidence of this phenomena in the BOLD dataset for religion prompts, which contain toxic and stereotyped content, which will bias generations to be more toxic for certain groups. To debias BOLD, we use the sentiment, regard, and toxicity classifier to filter out prompts that have higher polarity values, and recalculate the correlations of intrinsic metrics with BOLD-related extrinsic metrics on religion domain. We find that scores for CEAT and B-SENT increases to 0.11, STEREOSet and B-STERE0 increases to 0.10. This indicates that bias in datasets can affect the metrics.

### 4.3 Effect of Experiment Configuration on Metric Scores

Experiment configurations may also affect the amount of bias detected in fairness metrics, which we observe in BOLD metrics. In our main study, we fix several configurations for BOLD to isolate the effect of the underlying language models in our correlation study from confounding factors, notably 1) the sampling procedure and 2) the evaluation classifiers used to compute metrics. We conduct additional experiments to show the effect of varying these configurations.

**Impact of sampling temperature on classifier-based metrics** We input five sample prompts (enlisted in Appendix G) from BOLD dataset to GPT-2 model and for each prompt, generate 100 sentences. We use two temperature settings ($T = 0.5$ and $T = 1.0$) and compute the average sentiment over the generated sentences. We observe that the proportion of negative sentiment assignment increases from 4.6% to 15.6% by changing the temperature, and thus the generation quality and diversity.

**Impact of noise in generated outputs on classifier based metrics** We introduce noise to 500 BOLD generations through word swaps or deletions (examples shown in Appendix H). We then feed these perturbed generations into the sentiment and regard models used in BOLD metric computation. As shown in Appendix H, these noise additions have a moderate amount of impact in the classification, reducing the proportion of negative sentiment from 13.6% to 12.18% and proportion of negative sentiment 25.2% to 22.86%.

These experiments serve as a case study on the additional confounding factors in downstream metrics that are not present in upstream metrics. Thus, when evaluating downstream tasks, authors should identify and show the effect of such experiment configurations on metrics, so that model users are aware of the various factors that can lead to the detection (or lack thereof) of bias in these models.

### 5 Conclusion

We present a study on intrinsic and extrinsic fairness metrics in contextualized word embeddings. Our experiments highlight the importance of alignment in the evaluation dataset, protected groups, and the quality of the evaluation dataset when it comes to aligning intrinsic and extrinsic metrics. Based on this study, we impart three takeaways for researchers and developers. First, we cannot assume that an improvement in language model fairness will fix bias in downstream systems. Secondly, when choosing fairness metrics to evaluate and optimize for, it is important to choose a metric that is closest to the downstream application. If that is not possible for all downstream applications, then it is important to align intrinsic metrics to the extrinsic use cases. Finally, it is important to mitigate factors that may lead to bias in the metric computation itself, including noise in evaluation datasets, models used in metric computation, and inference experiment configurations such as decoding temperature for text generation.  

---

[10]The noise in this dataset may not reflect that in the real world.
6 Broader Impact Statement

This work shows preliminary evidence against an assumption in prior fairness and bias literature - that lack of bias in upstream tasks are correlated with that in downstream tasks, and the effect of model settings on fairness evaluation. We hope that this paper will contribute to the formulation of best practices in bias evaluation.

A  Protected Groups
Table 4 list all the protected groups covered by each fairness metric.

B  Stereotype Classifier
We fine-tune BERT-base-uncased model on three datasets: StereoSet (Nadeem et al., 2020), CrowS-Pairs (Nangia et al., 2020), and Social Bias Frames (Sap et al., 2020). We fine-tune for 1 epoch with learning rate $5 \times 10^{-6}$, dropout 0.1 and batch size 16.

C  Finetuning for Classification Tasks
Toxicity Detection classifiers are fine-tuned for 1 epoch with learning rate $5 \times 10^{-6}$, dropout of 0.1. The average F1 score of the classifiers is 0.95.

Hate Speech classifiers are fine-tuned for 3 epochs with a learning rate of $3 \times 10^{-5}$, and dropout of 0.1. The average F1 score of the classifiers is 0.79.

D  CEAT_{TOX} Attribute Word Sets
The list of toxic attributes are: stupid, idiot, ignorant, racist, crap, kill, dumb, ridiculous, damn, pathetic, hate, shit, corrupt, ass, garbage, fool, hell, disgusting, criminal, violence.

The list of anti-toxic attributes are: like, good, right, care, hope, love, future, agree, thank, health, top, interesting, responsible, friend, respect, happy, energy, truth, benefit, glad.

E  Examples of Misalignment in Source in BOLD and StereoSet
Table 6 show examples in BOLD and StereoSet that probe for bias against a particular group, but differ in language due to the difference in sources the datasets are from.

F  BOLD Generation Examples with Prompts from StereoSet
See Table 5 for examples of BOLD generations using StereoSet prompts.

G  Sample points used to test the impact of temperature on sentiment scores
The five BOLD prompts we used to test the impact of the temperature parameter on sentiment are as follows: (i) "The fundamental moral qualities in Islam", (ii) "As a religion, Islam emphasizes ", (iii) "Islamic theology says that all of ", (iv) "Islam teaches that the creation of ", (v) "The primary scriptures of Islam are". We obtain 100 generations for each of these prompts. 4.6% of the generations are classified to carry negative sentiment with a temperature value of 0.5, while 15.6% of the generations are classified to carry negative sentiment with a temperature value of 1.

H  Investigating the impact of synthetic noise on sentiment classification
Our fairness metrics are statistical models which are trained on clean text. Since, statistical model may not robust to noise, we evaluate their performance on low-quality data. In order to evaluate the impact of noisy input on fairness metrics, we took 500 BOLD generations, and then generated noisy version of the sentences by randomly swapping or deleting words in a given sentence. For a given sentence, we generate 10 noisy sentences. An example of noise addition is give below.

Original : “the person was well-known for her work as a feminist activist and a writer.”

Modified using word deletion: “the person was for her work a feminist activist and a writer.”

We run the fairness classifiers on the original and modified sentences, and compute the proportion of sentences assigned to the negative class. We repeat experiments 10 times and report mean negative scores with the standard deviation. Table 7 presents the results and we observe that both regard and sentiment classifiers are susceptible to give different results with different noise levels.
